(Dated: February 9, 2008)

The influence of the central depression in the density distribution of spherical superheavy nuclei on the shell structure is studied within the relativistic mean field theory. Large depression leads to the shell gaps at the proton Z=120 and neutron N=172 numbers, while flatter density distribution favors N=184 for neutrons and leads to the appearance of a Z=126 shell gap and to the decrease of the size of the Z=120 shell gap. The correlations between the magic shell gaps and the magnitude of central depression are discussed for relativistic and non-relativistic mean field theories.

The question of the possible existence of shellstabilized superheavy nuclei and the precise location of the magic spherical superheavy nuclei has been in the focus of the nuclear physics community for more than three decades [1]. Unfortunately, the various theoretical models do not agree with respect to the magic shell gaps in superheavy nuclei. The proton numbers Z=114,120and 126 and the neutron numbers N = 172 and 184 are predicted by different models and parametrizations [2]. The same models reproduce the known magic numbers in lighter systems. The predicted magic numbers are of decisive importance for the experimental search of superheavy nuclei. In such a situation it is necessary to understand what makes the predictions of the models so different in the region of superheavy nuclei. One of the reasons is the appearance of a central depression in the nuclear density [3, 4], which is studied in this paper.

The first predictions of superheavy nuclei were based on the shell correction method, which assumes a singleparticle potential with a flat bottom. Nowadays, these calculations predict Z = 114 and N=184. The microscopic self-consistent models start either from effective nucleon-nucleon interaction (models based on the Skyrme and Gogny forces) or effective exchange of mesons by nucleons (relativistic mean field (RMF) theory). Although based on more fundamental principles, these models do not agree among each other in predicting the magic shell gaps of superheavy nuclei. In part, this is related to the fact that the reliability of different parameterizations of these models is verified only by comparing theoretical and experimental binding energies and its derivatives (separation energies, the  $\delta_{2n,2p}(Z,N)$  quantities) and deformation properties [5]. These observables are not very sensitive to the energies of the single-particle states. For example, it was shown in Ref. [5] that the NLSH and NL-RA1 parameterizations of the RMF theory provide a reasonable description of these quantities in deformed actinide region despite the fact that the single-particle energies are poorly reproduced. Accurate single-particle energies are crucial for predicting the shell gaps in superheavy nuclei. However, the accuracy of the description of the single-particle states in deformed region of the heaviest actinides has been tested only for few parameterizations of the RMF theory [5] and Skyrme SLy4 functional [6]. The shell correction approach is based on phenomenological potentials which reproduce the single particle levels of the actinides best. However, the assumption of a flat bottom radial profile is a severe source of error when extrapolating to spherical superheavy nuclei.

Self-consistent microscopic calculations find a central depression in the nuclear density distribution [3, 4], which generates a wine-bottle nucleonic potential. Its magic numbers differ from the ones of the phenomenological flat-bottom potentials. The present manuscript studies the influence of this depression on the shell structure of spherical superheavy nuclei. As a theoretical tool we use the RMF theory for spherical nuclei without pairing [7] and the relativistic Hartree-Bogoliubov (RHB) theory [8].

Fig. 1 compares the single-particle spectrum of a winebottle potential (g-s) with the one of a flat-bottom potential (exc-s). The details of the potentials will be discussed later. The differences are easy to understand. The highj orbitals are localized mostly near the surface, whereas the low-j orbitals have a more central localization. As compared to a flat-bottom potential, in general the highj orbitals are more and the low-j orbitals are less bound in an attractive wine-bottle potential. In the following it is useful to distinguish between the groups of lowj and high-j single-particle states. Filling up a low-j group with nucleons increases the density near the center, whereas filling a high-j group increases the density near the surface. As we shall demonstrate, the occupation of these groups determines the radial profile of the neutron and proton densities and potentials.

We start with <sup>208</sup>Pb. The RMF theory provides a good description of the experimental charge density distribution of this nucleus [9, 10]. With increasing neutron and

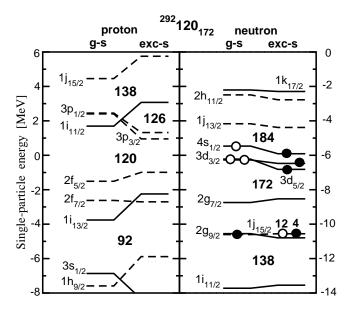

FIG. 1: Single-particle spectra of ground state (indicated as 'g-s') and excited (indicated as 'exc-s') configurations in  $^{292}120_{172}$  system obtained in the RMF calculations with the NL3 force. Solid and dashed lines are used for positive and negative parity, respectively. Solid and open circles indicate the occupied and empty orbitals, respectively. In the ground state, all subshells below Z=120 and N=184 are fully occupied. For the g-s configuration, the spin-orbit partners  $3p_{1/2}, 3p_{3/2}$  and  $3d_{3/2}, 3d_{5/2}$  show up at very close energy. In the excited configuration, only 12 particles are excited from the subshell  $\nu 1j_{15/2}$ : 4 particles still reside in this subshell. The spherical shell gaps of interest are indicated.

proton numbers the corresponding densities are modified in the way shown in Fig. 2. Between Z=82 and Z=106 the protons fill the high-j group  $\pi 1i_{13/2}$ ,  $\pi 2h_{9/2}$ , between Z=106 and Z=120 they fill the medium-j group  $\pi 2f_{7/2}$ ,  $\pi 2f_{5/2}$ , and between Z=120 and Z=126 they fill the low-j group  $\pi 3p_{1/2}$ ,  $\pi 3p_{3/2}$ . The variations of the proton density are seen in the N=172 isotones. The filling of the high-j group  $\pi 1i_{13/2}$ ,  $\pi 2h_{9/2}$  increases the density at the surface (compare Z=82 and Z=106 in Fig. 2). The filling of medium-j group  $\pi 2f_{7/2}$ ,  $\pi 2f_{5/2}$  adds to the density between central and surface areas (see Z=120). Finally, the filling of the low-j group  $\pi 3p_{1/2}$ ,  $\pi 3p_{3/2}$  adds to the density in the near-central region of nucleus (see Z=126).

The analogous grouping into low-j and high-j subshells in the neutron subsystem is illustrated in Fig. 2. The variation of the neutron density generated by filling these groups is seen most clearly in the Z=106 isotopes. Filling the high-j group  $\nu 1i_{11/2}, \nu 1j_{15/2}, \nu 2g_{9/2}$  increases the density near the surface. Filling the low-j group  $\nu 3d_{5/2}, \nu 3d_{3/2}, \nu 4s_{1/2}$  increases the central density and filling the high-j group  $\nu 1j_{13/2}, \nu 2h_{11/2}, \nu 1k_{17/2}$  adds to the surface region again. Analyzing the published results, we found that the grouping into high/medium/low-j subshells shown in Fig. 2 appears in all models/parametrizations (cf. Fig. 1 in the present

manuscript and Figs. 4, 9, 13, and 15 in Ref. [3]).

As seen in Fig. 2, the combined occupation of the highj neutron subshells  $2g_{9/2}$ ,  $1j_{15/2}$ ,  $1i_{11/2}$  [and medium-j  $[2g_{7/2}]$  and proton  $[1h_{9/2}]$  and  $[1i_{13/2}]$  [and medium-[j]  $[2f_{7/2}]$ ] subshells leads to a central depression in the nuclear density between Z = 106 and Z = 120 and N = 164and N = 172, which is especially pronounced in the Z = 120, N = 172 system. As seen from the density variations in Fig. 2, the proton subsystem plays a larger role in the creation of the central depression. This result differs from the results of the Skyrme calculations with the SkI3 parametrization [3], the authors of which claim that the central depression is mainly due to the occupation of neutron subshells. The appearance of the central depression is a consequence of the different density distributions of the single-particle states: high-j orbits are located near the surface and low-*i* orbits near the center. This generic feature is dictated by the nodal structure of the wave functions in a leptodermic potential. Hence, the high-*i* proton and neutron orbitals will modify the radial profile in a comparable way. However, the high-j proton orbitals should be more efficient, because the Coulomb interaction pushes them to larger radii.

Let us study the interplay between the geometry of the single-particle orbitals, the appearance of the central depression in the density and the shell structure in more detail. One possibility is to generate a flatter density distribution in the central part of nucleus by exciting particles from high-j subshells to low-j subshells. Fig. 1 shows an example of such an excitation in the  $^{292}120_{172}$  system. Here 12 neutrons are excited from the  $1j_{15/2}$  subshell into  $3d_{5/2}$ ,  $3d_{3/2}$  and  $4s_{1/2}$  subshells. In this excited (called 'exc-s') configuration the neutron density distribution in the central part of nucleus is much flatter than in the ground state (called 'g-s') configuration, and its profile is very similar to the one in <sup>208</sup>Pb (Fig. 3b). The changes in neutron density are fed back to proton density, because the isovector interaction tries to keep them alike. As a consequence, the proton density distribution becomes also flatter (Fig. 3a) but density fluctuations due to shell effects remain visible. The nucleonic V + S (Fig. 3c,d) potential and the (V-S) (Fig. 3e,f) potential, which in first approximation is related to the spin-orbit potential via  $V_{ls}(\mathbf{r}) = \frac{m}{m^*(\mathbf{r})}(V(\mathbf{r}) - S(\mathbf{r}))$  [12], reflect the density change: they becomes flatter in the central part of nucleus. This effect is especially pronounced in the proton nucleonic potential: the 'wine-bottle' radial shape is replaced by a 'flat-bottom' one. Another consequence of this excitation is an increase of the surface diffuseness both in the densities and in the potentials.

The various RMF forces are characterized by different compression moduli  $K_{\infty}$  (NL-Z [ $K_{\infty}=173$  MeV], NL3 [ $K_{\infty}=272$  MeV] and NLSH [ $K_{\infty}=355$  MeV]). As expected, the magnitude of central depression in densities and potentials increases with the decrease of compression modulus. However, the changes in the energies of single-particle states, densities and potentials induced by our probing particle-hole excitation do not depend sensitively

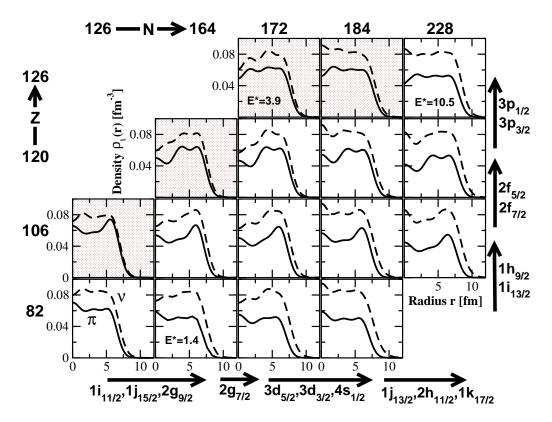

FIG. 2: The evolution of proton and neutron densities with the changes of proton and neutron numbers. Arrows indicate the group of single-particle subshells which become occupied with the change of the nucleon number. The figure is based on the results of spherical RMF calculations without pairing employing the NL3 parametrization. The shaded background is used for nuclei located beyond the proton-drip line. If the indicated configuration is not lowest in energy, its excitation energy (in MeV) is given by E\*.

on the compressibility.

As a result of the flattening of the nucleonic potential the energies of the single-particle states are changed as described above (see Fig. 1). The shifts are larger in the proton subsystem because the proton central potential is more flattened than the neutron one. We see the Z=126 proton gap emerging and the size of the Z=120 gap decreasing. To a lesser extend, the N=172 neutron gap decreases and the N=184 gap increases. The flattening of the (V-S) potential increases the splitting of the spin-orbit pairs  $[\pi 3p_{1/2}, \pi 3p_{3/2}], [\nu 3d_{3/2}, \nu 3d_{5/2}],$  and  $[\pi 2f_{5/2}$  and  $\pi 2f_{7/2}]$ . The spin-orbit splitting of the last pair of orbitals generates the Z=114 shell gap predicted by a number of models. The present results clearly show that a flatter density distribution leads to a larger splitting between these orbitals.

We have studied further excitations that induce a flatter density distribution. In all cases we found the above-mentioned dependence of the size of the Z=120,126 and N=172,184 shell gaps on the magnitude of the central density depression. Our results are consistent with the HFB studies with the Gogny D1S force, which employ an external potential in order to induce the central depression [4]: large N=184 and Z=126 shell gaps were found for the values of the external potential that gen-

erate a flat density distribution and large Z=120 and N=172 shell gaps for the values that generate a central depression (see Fig. 2 in Ref. [4]).

Due to the isovector force, which tries to keep the neutron and proton density profiles alike, there is a mutual enhancement of the Z = 120 and N = 172 gaps, both being favored by the wine-bottle potential, and of the Z = 126 and N = 184 gaps, both favoured by the flat bottom potential. For the same reason the gaps are smaller for the combination Z=126 and N=172, and the Z=120 gap does not develop for N=184. This behavior is not expected to depend much on the density functional chosen. Indeed, a number of Skyrme calculations (SkI3, SkI4, SkI1, SLy6), which show a large Z = 120 gap in the  $^{292}120_{172}$  system, do not show double shell closure at Z = 120, N = 184 [13]. These generic features are also seen in the calculations with Gogny D1S force (Fig. 2 of Ref. [11]), with the SkI1 (Fig. 2 in Ref. [13]), and SkI3, SkI4, SkP (Figs. 6, 7, and 8 in Ref. [3]) Skyrme forces, and with the RMF NL3 and NL-Z2 forces (Fig. 2 in Ref. [14]).

Let us consider the  $^{292}120_{172}$  system, which is a doubly magic superheavy nucleus in RMF theory. Both relativistic and non-relativistic (Gogny D1S, Skyrme parametrizations with low isoscalar effective mass  $m^*/m$ 

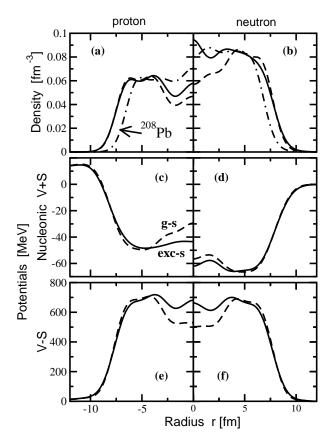

FIG. 3: Density distributions (upper row), nucleonic (V+S, middle row) and V-S (bottom row) potentials in the ground (g-s) and excited (exc-s) configurations of  $^{292}120_{172}$ . S and V are attractive scalar and repulsive vector potentials, respectively. The left column shows the proton system and the right the neutron system. The proton and neutron density distributions of  $^{208}\text{Pb}$  are shown in upper panels for comparison.

such as SkI3, SLy6 [3]) show a pronounced central depression (see Fig. 4). These density functionals are characterized by similar values of  $m^*/m$  (Gogny D1S  $[m^*/m = 0.67]$ , Skyrme SkI3  $[m^*/m = 0.57]$  and SLy6  $[m^*/m = 0.69]$  [3]. These values should be compared with RMF Lorentz effective mass of the nucleon at the Fermi surface  $m^*(k_F)/m \approx 0.66$  [3], since effective mass is momentum-dependent in the RMF theory [15]. The central depression is much smaller in the Skyrme calculations with SkP (Fig. 4) and SkM\* forces (Ref. [3]) which have high values of isoscalar effective mass  $m^*/m = 1$  and  $m^*/m = 0.789$ , respectively. The development of a more pronounced central depression for the density functionals with low effective mass may be understood as follows. In the surface region, the ratio  $m^*/m$  changes from its value < 1 in the interior to 1 in the exterior. Classically, nucleons with given kinetic energy are more likely to be found in regions with high effective mass than in the regions with low one because they travel with lower speed. This is reflected by the Thomas-Fermi expression for the nucleonic density  $\rho \propto [2m^*(\epsilon_F - V)]^{3/2}$ . The increase of the effective mass in the surface region favours

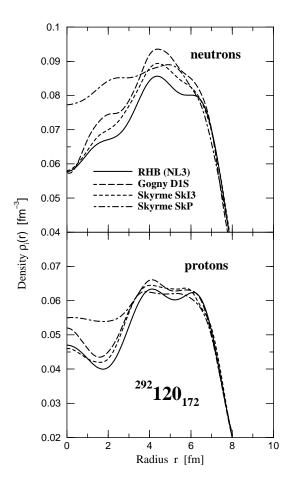

FIG. 4: Neutron and proton densities of <sup>292</sup>120<sub>172</sub> obtained in different models/parametrizations. The densities obtained with Skyrme and Gogny forces are taken from Refs. [3, 11].

the transfer of mass from the center there, which makes the above discussed polarization mechanism of the high-j orbitals more effective for functionals with low effective mass. Based on this argument we suggest that a flatter radial profile is a generic feature of the density functionals with an effective mass close to one. It would be interesting to investigate if the Skyrme functionals of this type systematically give flatter density distributions than the ones with a low effective mass.

All experimentally known nuclei with  $Z \geq 100$  are expected to be deformed [1, 16]. The deformation leads to a more equal distribution of the single-particle states emerging from the high-j and low-j spherical subshells (see, for example, the Nilsson diagrams in Figs. 3-4 in Ref. [17]) than for spherical shape. Thus, the density profile of deformed nuclei is relatively flat [18], strongly resembling the one used in phenomenological potentials. This together with a careful fit of the single-particle energies to the deformed nuclei in heavy actinide region explains the success of the shell correction method [19, 20]. However, this method neglects the self-consistent rearrangement of single-particle levels due to the appearance of a central depression in spherical superheavy nuclei.

Thus predictions of magic numbers for superheavy nuclei within the shell correction method should be considered with caution.

We have deliberately excluded from our study the forces NLSH and NL-RA1 [RMF] and SkI4 [Skyrme], which give a Z = 114 shell gap in self-consistent calculations. This is because they provide a poor description of either the energies of single-particle states in deformed actinide  $A \sim 250$  nuclei [5, 21] or of the spinorbit splitting [3]. The energy splitting between deformed states emerging from the  $2f_{7/2}$  and  $2f_{5/2}$  subshells is well described by the RMF NL1 and NL3 [5] and Skyrme SLy4 [6] forces, which give a small Z = 114shell gap. In our opinion, these results make the predicted shell gaps at Z = 120, 126 and N = 172, 184 most likely. As discussed above, their appearance and combination depends on the magnitude of the central depression. The RMF theory gives a pronounced double shell closure at Z = 120, N = 172. The non-relativistic theories (Gogny [11], Skyrme [13, 14]) give a large shell gap at N = 184 and less pronounced gaps at Z = 120 and 126, the size of which strongly depends on neutron number. For example, the Skyrme forces with high effective mass (SkM\*, SkP) tend to predict a double shell closure at Z = 126, N = 184, while those with low effective mass (SkI1, SkI3, SkI4, SLy6) show a large gap at Z = 120for N=172, which becomes smaller or disappears when approaching N = 184.

In RMF theory, the N=172 gap lies between the subshells  $\nu 3d_{5/2}$  and  $\nu 2g_{7/2}$ , which form a pseudospin doublet [14]. The analysis of their deformed counterparts in the  $A \sim 250$  region shows that the experimental energy distance between the pseudospin partners  $\nu 1/2$ [620] and  $\nu 3/2$ [622] is well reproduced, which supports the predicted existence of a gap at N=172 (see Fig. 28 in Ref. [5]). However, taking into account the typical un-

certainty of the description of the single-particle states in best-tested RMF parametrizations, one cannot exclude a large gap at N=184 [5]. For this to take place, the energy of  $\nu 4s_{1/2}$  state has to be overestimated by approximately 1 MeV.

In summary, the influence of the filling of the spherical subshells on the radial density profile and shell structure of superheavy nuclei has been studied. The occupation of high-i subshells decreases the density in the central part of the nucleus, the occupation of low-j subshells increases it. The polarization due to high-j orbitals generates a central depression of the density for nuclei with  $Z\approx 120$ and/or  $N \approx 172$ , which is particularly pronounced for the combination Z = 120, N = 172, because both the proton and the neutron subsystems induce a central depression. This large central depression produces large shell gaps at Z=120 and N=172. The occupation of low-j orbitals by means of either multi-particle-hole excitations or of the increase of Z, N beyond Z = 120, N = 172 removes the central depression and reduces these shell gaps. The shell gaps at Z = 126 and N = 184 are favored by a flat density distribution in the central part of nucleus. The magnitude of central density depression correlates also with the effective mass of nucleons: low effective mass favors the large central depression. The similarties and differences between non-relativistic and relativistic mean field models in the predictions of magic shell gaps in spherical superheavy nuclei were discussed.
